ABSTRACT

Haloacetamides (HAMS) are cytotoxic, genotoxic, and mutagenic byproducts of drinking water disinfection. They are soft electrophilic compounds that form covalent bonds with the free thiol/thiolate in cysteine residues through an S_n2 reaction mechanism. Toxicity of the monohalogenated HAMS (iodoacetamide, IAM; bromoacetamide, BAM; or chloroacetamide, CAM) varied depending on the halogen substituent. The aim of this research was to investigate how the halogen atom affects the reactivity and toxicological properties of HAMS, measured as induction of oxidative/electrophilic stress response and genotoxicity. Additionally, we wanted to determine how well in silico estimates of electrophilic softness matched thiol/thiolate reactivity and in vitro toxicological endpoints. Each of the HAMS significantly induced nuclear Rad51 accumulation and ARE signaling activity compared to a negative control. The rank order of effect was IAM > BAM > CAM for Rad51, and BAM ≈ IAM > CAM for ARE. In general, electrophilic softness and in chemico thiol/thiolate reactivity provided a qualitative indicator of toxicity, as the softer electrophiles IAM and BAM were more thiol/thiolate reactive and were more toxic than CAM.

Introduction

Disinfection of municipal drinking water is an essential safeguard of public health (Calderon, 2000). However, the addition of disinfectants to source waters containing organic and inorganic precursor molecules generates a mixture of toxic halogenated byproducts (Krasner et al., 1989). Many of these disinfection byproducts (DBPs) are cytotoxic, genotoxic, and mutagenic in vitro, and some are carcinogenic in rodents (Richardson et al., 2007). Moreover, epidemiologic studies suggested long-term exposures to DBPs increased risk of bladder cancer (Michaud et al., 2007; Villanueva et al., 2007). Still, the mechanisms of toxicity leading to the observed adverse effects are not fully understood, making it difficult to establish effective interventions. Additionally, since DBPs are formed at concentrations below their individual adverse effect levels, it is unlikely that any...

individual DBP can account for the aforementioned observed adverse effects highlighting the need for understanding the toxic effect of the whole mixture (Bull, 2006; Simmons et al., 2002). Identification of chemical groups that share a common mechanism within the DBP mixture would provide a better understanding of the mixture toxicity (U.S. EPA, 2002) and could provide valuable insight on how to improve chemical regulation.

Several DBPs can be classified as soft electrophilic compounds (highly polarizable chemicals deficient in electrons) that preferentially react with biological soft nucleophiles (e.g., thiol/thiolate groups) forming covalent bonds (Pearson, 1963). For example, many DBPs share an α-halogenated carbonyl motif identified as a structural predictor of thiol (glutathione (GSH)) reactivity (Hughes et al., 2015). Additionally, cytotoxicity and genotoxicity correlated with predicted S4p2 reactivity for several α-halogenated carbonyl (or nitrile) containing DBP chemical classes including haloacetonitriles (HANs), haloacetamides (HAMS), and halocetic acids (HAAs) (Muehler et al., 2007; Plewa et al., 2008, 2010). Genotoxicity induced by the α-halogenated carbonyl (or nitrile) containing DBPs, bromoacetamide (BAM), and bromoacetonitrile (BAN) were significantly reduced by co-treating with N-acetylcysteine (NAC) (Pals et al., 2016). Therefore, reactivity seems to play a significant role in the toxicity of DBPs, where directly perturbing the intracellular thiol pool through alkylation of cellular thiol/thiolates leads to a toxic response by disrupting various cellular processes (Schultz et al., 2006). Moreover, GSH depletion is observed in the progression of several diseases including cancer, cardiovascular, and neurodegenerative diseases (Ballatori et al., 2009).

Furthermore, reactive electrophiles with common cellular targets present an ideal opportunity for additive or synergistic toxicity (U.S. EPA, 2002). In fact, experiments with α,β-unsaturated carbonyl derivatives, showed additive toxicity in binary and ternary mixtures in vitro and in an in vivo model (Zhang et al., 2016). Work by Dawson and colleagues showed that HANs and halogenated ethyl acetates (α-halogenated carbonyl containing compounds) generated, in some cases, dose additive toxicity within and among these chemical classes (Dawson et al., 2010, 2011, 2014). Additive genotoxicity was observed in binary mixtures of BAM and BAN (Pals et al., 2016).

Soft electrophile reactivity can be predicted using in silico methods based on Hard Soft Acid Base (HSAB) theory (Karelson et al., 1996). HSAB theory makes use of frontier molecular orbital (FMO) energies to predict reactivity between electrophile–nucleophile pairs (Karelson et al., 1996). Several parameters for reactivity based on FMO energies were developed and utilized in Quantitative Structure Activity Relationship (QSAR) applications (Schwöbel et al., 2011); however, in its basic form, HSAB theory suggests that an electrophile is soft if it has a low energy lowest unoccupied molecular orbital (ELUMO) (Karelson et al., 1996). Estimations of ELUMO, therefore, provide a theoretical method for identifying soft electrophiles among identified DBPs. Our previous work showed that ELUMO was a useful predictor of thiol reactivity and genotoxicity in a set of mono-brominated DBPs (bromoacetic acid, BAM, and BAN) (Pals et al., 2016). However, because reactivity of alkyl halides is dependent on halogen leaving efficiency, the effect of variable halogen substitution requires additional investigation. The set of monoHAMs, iodoacetamide (IAM), BAM, and chloroacetamide (CAM), isolates the effect the halogen substituent asserts on thiol/thiolate reactivity and toxicity, and allows us to evaluate in silico softness parameters as predictors of these effects. In this study we measured the ability of each monoHAM to generate an Antioxidant Response Element (ARE) driven stress response, and to generate toxicity as DNA double strand breaks. We then compared toxic potencies with in chemico reactivity and in silico parameters derived from FMO energies to determine their ability to predict in vitro effects.

1. Experimental

1.1. General reagents

General laboratory reagents were purchased from Fisher Scientific Co. (Itasca, IL) or Sigma Aldrich Co. (St. Louis, MO). IAM, BAM, CAM, DTNB (5,5′-dithiobis (2-nitrobenzoic acid)) and NAC were purchased from Sigma-Aldrich (St. Louis, MO).

1.2. In silico estimates of FMO energies

FMO energies, including energy of the highest occupied molecular orbital (EHOMO) and ELUMO were estimated using density function B3LYP 6-311+G**, from Hartree Fock 6-311+G** equilibrium geometries with Spartan 10 software (Wavefunction Inc., Irvine, CA). Electrophilic hardness (η), softness (α), chemical potential (μ), and electrophilic index (ω) were calculated using Eqs. (1)–(4) respectively.

**Hardness (η) = [ELUMO − EHOMO] / 2**

(1)

**Softness (α) = 1 / η**

(2)

**Chemical Potential (μ) = [ELUMO + EHOMO] / 2**

(3)

**Electrophilic Index (ω) = μ² / 2η**

(4)

1.3. NAC reactivity

NAC served as a model soft nucleophile to determine HAM electrophilic reactivity. After exposure to the HAMs (30 min), the remaining free thiol was quantified with Ellman’s reagent (Ellman, 1959) with minor modifications of the previously published protocol (Pals et al., 2016). For these experiments, Ellman’s reagent was prepared from stock solutions of 100 mM DTNB in dimethyl sulfoxide (DMSO), and 200 mM EDTA (ethylene diaminetetraacetic acid) in deionized water diluted to 1 and 0.1 mM, respectively, in 200 mM Tris buffered EDTA (pH 8.0). Fresh 1 M stock solutions of NAC or HAM were prepared in DMSO for each experiment. HAMs and NAC were further diluted into 200 mM Tris pH 8.0. Each HAM, in a range of concentrations from 0 to 2000 μM, was mixed with 400 μM NAC in a total volume of 50 μL 200 mM Tris pH 8.0 in a 96 well microplate. Reactions occurred at room temperature with orbital shaking at 250 r/min. After the reaction time expired, 50 μL of Ellman’s reagent was added to the wells. After 3 min at 250 r/min the absorbance at 412 nm (A412) was measured for each well with a Spectramax Paradigm plate reader (Molecular Devices, Sunnyvale, CA).
Blank reactions (NAC + Tris buffer + Ellman’s reagent) were subtracted from the data. The blank adjusted A$_{412}$ for the negative control was set to 100% free thiol, and the remaining data normalized to its concurrent negative control. Experiments were repeated three times, one well/concentration/experiment.

1.4. ARE signaling activity assay

Cellular oxidative/electrophilic stress responses generated by the HAMs were measured using the CellSensor ARE-bla HepG2 cell line (Life Technologies, Madison, WI). This cell line contains a stably integrated β-lactamase gene whose transcription is controlled by cis acting ARE coding regions. Briefly, cells were plated at 2000/well/5 μL in 1536 well black-clear bottom plates (Greiner Bio-One North America, Monroe, NC) and incubated at 37°C, 5% CO$_2$ for 5 hr. Twenty three nanoliters of HAM or a positive control, β-naphthoflavone, were transferred to each well using a pintool (Kalypsys, San Diego, CA). Each HAM was tested at 23 concentrations from 500 μM to 0.12 nM. Cells in assay plates were incubated at 37°C, 5% CO$_2$ for 16 hr. After the incubation period, 1 μL of CCF4 dye (Life Technologies) was added to each well and the plate was incubated at room temperature for 2 hr. Fluorescence intensity at 460 and 530 nm emissions was measured after 405 nm excitation by an Envision plate reader (PerkinElmer, Boston, MA) followed by an addition of 4 μL/well of cell viability reagent (CellTiter-Glo, Promega, Madison, WI). The plates were incubated for 30 min at room temperature and luminescence intensity was read using a ViewLux plate reader (Perkin-Elmer). For the ARE-bla assay, data were expressed as the ratio of the 460/530 emission values, normalized to the positive control and solvent control responses (23 μM β-naphthoflavone, 100% and DMSO, 0%, respectively). For cytotoxicity, data were normalized to 100% for the DMSO control, and to 0% for the cytotoxic control (92 M tetraoctyl ammonium bromide). At least 4 independent experiments were repeated in duplicate (two plates per experiment; one well/concentration/plate).

1.5. Rad51 redistribution assay

The Rad51 Redistribution Assay (Thermo Scientific, Rockford, IL) evaluates DNA double strand breaks by measuring the accumulation of Rad51 in nuclear foci in recombinant SW480 cells stably expressing human Rad51 fused to the C-terminus of enhanced green fluorescent protein. SW480 cells containing the Rad51 construct (1500 cells/well/5 μL) were plated overnight at 37°C, 5% CO$_2$ and then treated with HAM (4.6 mM camptothecin) for 24 hr. After that, cells were fixed and Hoechst stain (1 μM final concentration) was added for 30 min. After 3 washes with phosphate buffered saline (PBS), plates were sealed and kept at 4°C until read. Cells were read using Arrayscan™ system (ThermoFisher Scientific, Waltham, MA) (400 cells minimum) with 2 colors (blue and green). Images were analyzed and data were collected using the compartmental analysis application (ThermoFisher) that allows the simultaneous quantification of nuclei and the presence of foci in each nucleus. The nuclear area is defined by the Hoechst stain and green foci are counted inside the nuclear area. Experiments were repeated in duplicate, with one well/concentration/plate.

1.6. Statistics

All statistical analyses were performed using SigmaPlot 11.0 (Systat Software Inc., San Jose, CA). To determine significant reduction of free thiol with respect to negative controls, a one way analysis of variance (ANOVA) was conducted. When a significant ($p \leq 0.05$) F value was obtained, a Holm Sidak comparison was used to compare to the negative control values. Before linear regression, data with <45% thiol were removed to eliminate plateau effects from diminished reagents. The reactive potency ($RC_{50}$) values were calculated from the linear regression equations.

ARE activity and Rad51 pit counts were normalized as a percent of a positive control (23 μM β-naphthoflavone or 10 μM camptothecin, respectively) and plotted vs. HAM concentration. For each HAM, 3-parameter sigmoidal regression was fit to the data and EC$_{50}$ values were calculated from the corresponding regression equation.

2. Results and discussion

This work aimed to evaluate in silico parameters as predictors of thiol/thiolate reactivity, antioxidant/electrophilic stress response, and genotoxicity in a set of three mono-HAMs. Compounds containing an α-halogenated carbonyl group are predicted to be thiol reactive (Hughes et al., 2015) to varying degrees based on the leaving efficiency of the halogen substituent (Plewa et al., 2008; Schultz et al., 2007). IAM, BAM, and CAM, which are genotoxic and mutagenic DBPs, contain this α-halogenated carbonyl motif and showed toxicity dependent on S$_0$2 reactivity (Plewa et al., 2008). Selecting these three compounds for analysis allowed for the isolation of the halogen substituent as a single variable in a study of the relationship between reactivity and toxicity.

2.1. In chemico reactivity

Non-enzymatic reactivity was measured as the percent reduction of free thiol from the initial NAC concentration after a 30 min reaction period. Reactivity followed the expected pattern, with the rank order of IAM > BAM > CAM. IAM and BAM significantly ($p < 0.001$) reduced percent free thiol at all assayed concentrations (200–2000 μM); CAM did not deplete free thiol at any concentration. Linear regression equations ($R^2 \geq 0.99$) for IAM and BAM were used to calculate RC$_{50}$. The RC$_{50}$ values, concentrations that eliminated 50% of the initial free thiol, were 0.559 and 0.973 mM for IAM and BAM respectively (Table 1). These data were consistent with the I > Br > Cl pattern of reactivity in a larger group of α-halogenated carbonyl compounds (Dawson et al., 2010, 2011; Schultz et al., 2007).

Schultz and coworkers reported that CAM depleted free thiol using GSH as a model nucleophile and a 2 hr reaction time; in their study the reactive potency was much greater for BAM (EC$_{50}$ 0.26 mM) than CAM (EC$_{50}$ 16.99 mM) (Schultz et al., 2007). The lack of reactivity of CAM in the present study may be due to the use of a shorter reaction time (30 min) or a lower concentration range.
and BAM were the most reactive in chemico, and were also more potent activators of ARE than CAM. BAM was less reactive than IAM in chemico but was essentially an equally potent inducer of ARE activity. This observation could indicate that BAM reactivity is sufficient to alkylate susceptible thiols/thiolates to generate maximum effect, thus the increased reactive potential of IAM is not reflected as increased stress response or toxicity. It could also indicate that other factors independent of reactivity (e.g., log P) could play an important role in monoHAM induced toxicity.

Similar to the monoHAs, the monohalogenated acetic acids (monoHAAs) activated ARE signaling with an I > Br > Cl pattern of potency (Pals et al., 2013). Many additional DBPs with GSH reactive molecular motifs activated ARE signaling (Stalter et al., 2016). Furthermore, ARE activity correlated with increased mixture toxicity as water moved through stages of the disinfection process (Neale et al., 2012), suggesting that oxidative or electrophilic stress is related to total toxicity within the DBP mixture.

2.3. Rad51 foci formation

As part of a multicomponent system to initiate and facilitate DNA damage signaling and repair, Rad51 accumulates as foci near DNA double strand breaks (Haaf et al., 1995). Accumulation of nuclear Rad51, therefore, can be used as a measure of DNA damage. Fig. 3 displays nuclear Rad51 foci with respect to HAM concentration normalized to a positive control (10 µM camptothecin). Each of the monoHAs generated a concentration dependent increase of nuclear Rad51 foci. IAM, BAM and CAM generated EC50 values of 3.80 × 10^{-6}, 5.69 × 10^{-6}, and 3.00 × 10^{-4} M, respectively. These data were consistent with DNA damage generated in Chinese hamster ovary cells; genotoxic potency (equivalent to EC50) values of 3.41 × 10^{-5}, 3.68 × 10^{-5}, and 1.38 × 10^{-3} M were reported for IAM, BAM, and CAM, respectively (Plew et al., 2008). These data showed a similar pattern where BAM and IAM generated similar toxicity with CAM significantly less genotoxic. Genotoxicity (indirectly measured as Rad51 foci formation) for these compounds seems to be related to thiol/thiolate reactivity with a threshold above which additional reactivity no longer generates additional in vitro effects.

2.4. In silico estimates of FMO energies, electrophilic softness, and reactivity

Selected molecular parameters along with potency values for in chemico reactivity, activation of ARE signaling activity, and Rad51 foci formation are listed in Table 1. The in silico parameters (Table 1) identified an IAM > BAM > CAM rank

ARE: Antioxidant Response Element; IAM: iodoacetamide; BAM: bromoacetamide; CAM: chloroacetamide.
order of electrophilic softness. This pattern matched the measured in chemico reactivity; a similar trend was previously observed where the low ELUMO compounds BAN and BAM were more thiol reactive than bromoacetate, which had a higher LUMO energy (Pals et al., 2016). These observations suggest that electrophilic softness is a useful indicator of thiol/thiolate reactivity in chemico for α-halogenated carbonyl/nitrile containing DBPs.

The softer and more reactive electrophiles IAM and BAM were significantly more potent inducers of ARE signaling activity and Rad51 foci than the less reactive CAM, however, the rank order of softness (or in chemico reactivity) was not maintained in vitro, as BAM and IAM were equally potent inducers of ARE signaling activity (Table 1). LoPachin and others showed a direct relationship between in silico predictions of electrophilic softness and cytotoxicity for α,β-unsaturated carbonyl compounds (Chan et al., 2008; LoPachin et al., 2009). These compounds react through a Michael addition mechanism that may be better suited for modeling with FMO energies. The S$_2$2 reaction mechanism favored by the monoHAMS is dependent on the leaving efficiency of the halogen (Plewa et al., 2008). This along with additional variables that affect reactivity, or bioavailability independent of FMO energies, such as steric hindrance, or log P, likely modify the relationship between electrophilic softness and in vitro effects (Tuppurainen, 1999). In general we observe that in silico estimates of electrophilic softness provide a useful qualitative predictor of thiol/thiolate reactivity in chemico and toxicity for electrophilic compounds, however, additional consideration should be given to variables that contribute to reactivity and or toxicity independent of FMO energy.

3. Conclusion

The aim of this research was to investigate the relationship between thiol/thiolate reactivity, activation of ARE regulated stress response, and Rad51 foci formation. Within the selected group of HAMs, reactivity parameters derived from FMO energies as well as in chemico thiol/thiolate reactivity were able to qualitatively predict activation of antioxidant/electrophilic stress response and genotoxicity (measured as Rad51 foci formation). The softer electrophiles, IAM and BAM, were more reactive with our model soft nucleophile and were more potent inducers of cellular stress and Rad51 foci when compared to the less reactive CAM.

The ability to identify mechanisms of toxic activity from molecular or physicochemical descriptors provides a useful tool in mixture toxicity. Both in silico and in chemico reactivity are useful descriptors to screen/identify toxicants that act by disrupting cellular processes dependent on free thiol/thiolate chemistry. However, this approach carries its own limitations. In the case of in silico parameters, additional consideration should be given to factors independent of ELUMO when predicting electrophilic reactivity, and in the case of in chemico reactivity, experimental conditions (i.e., concentration and reaction time) should be considered to avoid false negative classification.
We wish to thank the Chemistry Department at Eastern Illinois University for access to and assistance using Spartan 10 software.
